Intensity Normalization

Intensity normalization

- Conventional MRI intensites (T1-w, T2-w, PD, FLAIR) are acquired in arbitrary units
- Images are not comparable across scanners, subjects, and visits, even when the same protocol is used.
- Intensity normalization brings the intensities to a common scale.

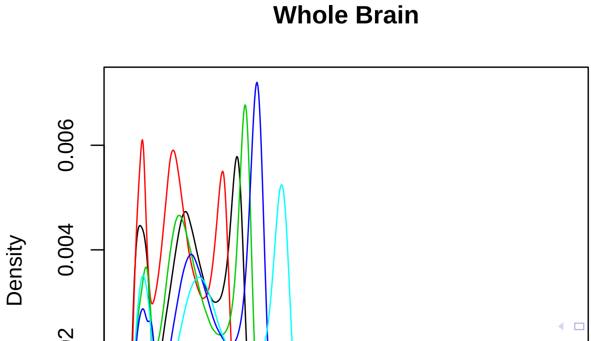
Goals of this tutorial

- Visualize intensity distributions from different subjects and tissue classes.
- Apply the WhiteStripe intensity normalization (Shinohara et al. 2014).

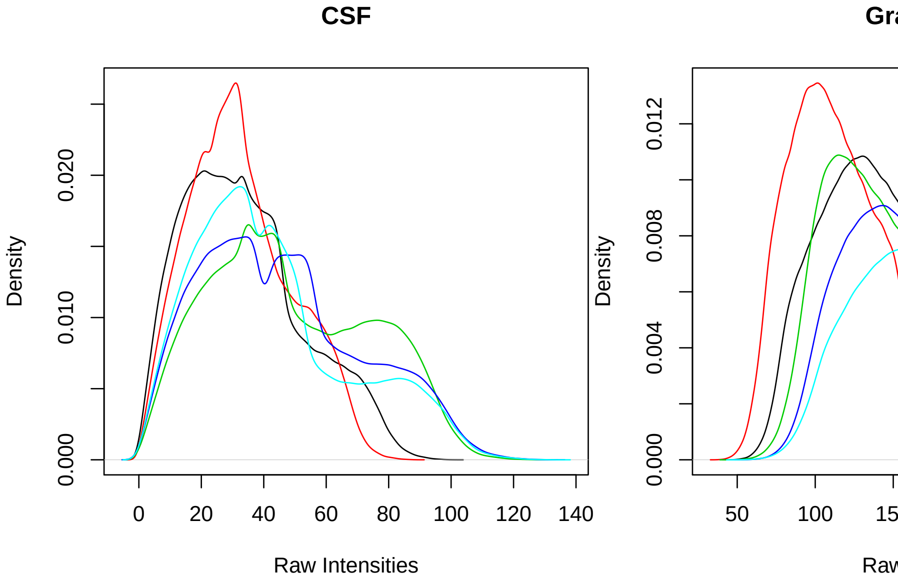
Visualizing whole-brain intensities

- For the moment, we will work with the T1-w images from the training data.
- Full brain densities are mixtures of the three tissue class distributions.
- The following includes only voxels located inside the brain mask.

```
plot_densities(dens)
```

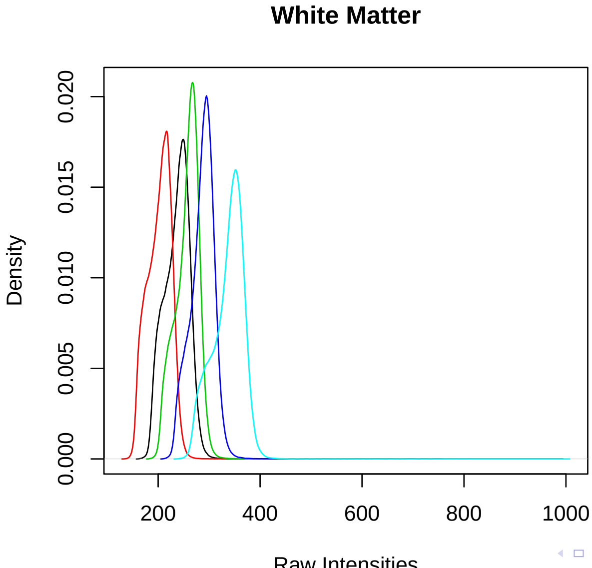


Visualizing the intensities by tissue class



Visualizing the intensities by tissue class

- Notice the complete non-overlap between some subjects' white matter distributions.



Whole-brain normalization

- Let's Z-score each voxel using mean μ_{WB} and standard deviation σ_{WB} computed from all voxels in the brain mask.

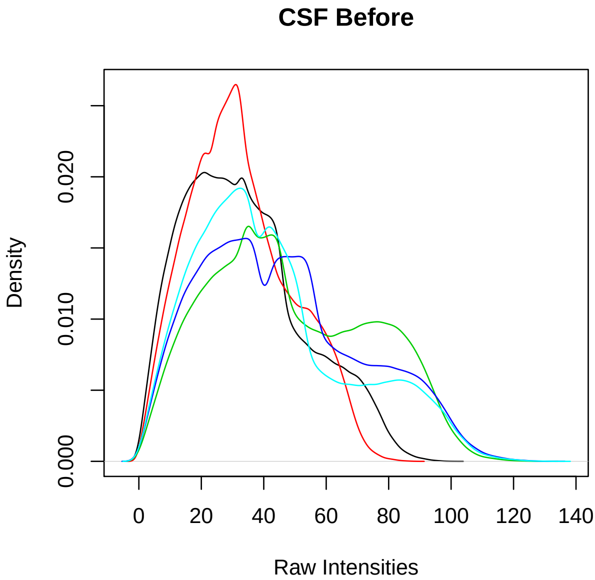
$$T1_{i,v}^{WB} = (T1_{i,v} - \mu_{WB})/\sigma_{WB}$$

- `zscore_img` is a function in `neurobase` that does this.
- It takes an image and a binary mask. The default is to use all voxels in the brain mask.
- Other options allow for more robust transformations, such as using the median to center, IQR to scale, etc.

```
zscore_img(img = img, mask = mask)
```

Whole-brain normalized intensities

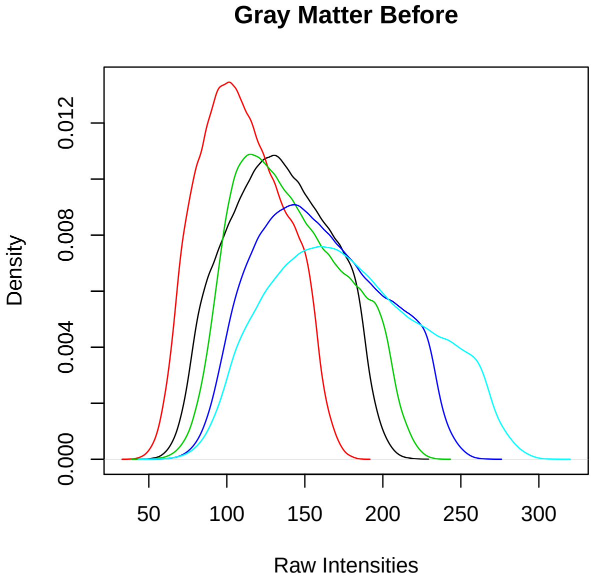
- CSF distributions are more comparable.



CSF After

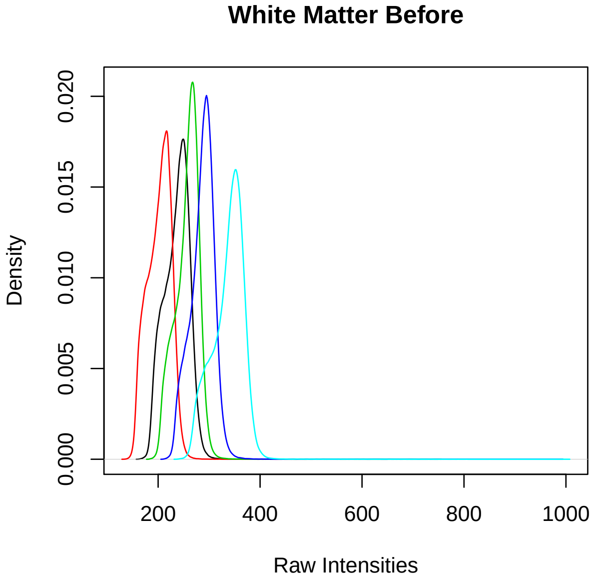
Whole-brain normalized intensities

- Gray matter distributions are more comparable.



Whole-brain normalized intensities

- White matter distributions are more comparable.



Why White Stripe?

- Whole-brain normalization may be sensitive to outliers.
- Thus, the estimated mean an variance can be highly variable across subjects, leading to
- White Stripe is based on parameters obtained from a sample of normal appearing white matter (NAWM), which is robust to outliers.
- The idea is to make normal appearing white matter comparable across subjects and visits.

White Stripe normalization

- We normalize each voxel using the mean μ_{WS} and standard deviation σ_{WS} computed from normal appearing white matter voxels.

$$T1_{i,v}^{WS} = (T1_{i,v} - \mu_{WS})/\sigma_{WS}$$

- After normalization, NAWM will have a standard normal distribution and units will be in standard deviations of NAWM.
- Gray matter and CSF distributions may not be comparable after White Stripe.

White Stripe normalization code

```
ind = whitestripe(img = t1, type = "T1",
    stripped = TRUE)$whitestripe.ind
ws_t1 = whitestripe_norm(t1, indices = ind)
}
```

- The `whitestripe` function takes an image, image type (in our case T1), and a logical indicating whether the image has been skull stripped.
- The indicies of voxels in the NAWM used for estimating the normalization parameters are located in the list element `$whitestripe.ind`.
- The function `whitestripe_norm` takes an image and the indicies from a call to `whitestripe` and returns the White Stripe normalized image as a nifti.

Conclusions

- Intensity normalization is an important step in any image analysis with more than one subject or time point to ensure comparability across images.
- White Stripe normalization may work better and have better interpretation than whole-brain normalization for subsequent lesion segmentation algorithms and analysis.
- Newer normalization methods exist. One is RAVEL, which extend WhiteStripe to make intensites comparable across subjects for all tissues (Fortin et al. 2016).
